Abstract

Cylindrical storage tanks are widely used for various types of liquids, including hazardous contents, thus requiring suitable and careful design for seismic actions. The study herein presented deals with the dynamic analysis of a ground-based horizontal cylindrical tank containing butane and with its safety verification. The analyses are based on a detailed finite element (FE) model; a simplified one-degree-of-freedom idealization is also set up and used for verification of the FE results. Particular attention is paid to sloshing and asynchronous seismic input effects. Sloshing effects are investigated according to the current literature state of the art. An efficient methodology based on an “impulsive-convective” decomposition of the container-fluid motion is adopted for the calculation of the seismic force. The effects of asynchronous ground motion are studied by suitable pseudo-static analyses. Comparison between seismic action effects, obtained with and without consideration of sloshing and asynchronous seismic input, shows a rather important influence of these conditions on the final results.

Keywords Cylindrical tank · Sloshing · Asynchronous seismic action · FE modeling · Seismic behavior

Introduction

Seismic loading can induce large damages in industrial facilities and their complex components (Babič and Dolšek 2016; Demartino et al. 2017a, b; Nuti et al. 2009). The loss of the structural integrity of these structures can have severe consequences on the population, the environment and the economy (Krausmann et al. 2010; Fiorentino et al. 2015; Rodrigues et al. 2017). Looking at power/chemical/petrochemical plants, storage tanks containers are widely employed. These hold liquids, compressed gases or mediums used for the short- or long-term storage of heat or cold.

Liquid storage tanks and piping systems are considered as critical components of those industrial facilities (Vathi et al. 2017; Bakalis et al. 2017).

The seismic response of tanks has been widely studied in the past starting from the pioneering studies of Housner (1957, 1963). In particular, Housner (1957) first presented the simplified formulae to compute the dynamic pressures developed on accelerated liquid containers and successively (Housner 1963) studied the dynamic behavior of ground-supported elevated water tanks considering equivalent spring–mass systems. Current practice for the seismic design of storage tanks is mainly based on Appendix E of API 650 (2007) standard and on Eurocode 8 (1998). Generally speaking, there are many different types of equipment used for the storage of liquids and gases. The characteristics of the different tanks adopted mainly depend on: (a) the quantity of fluid being stored, (b) the nature of the fluid, (c) the physical state of the fluid and (d) the temperature and pressure. In industrial plants, gases are usually stored under high-pressure, often in liquid form since the volume is largely reduced. Within this framework, ground-based horizontal cylindrical tanks resting upon two supports are used mainly for storage of various liquids. The capacity of such tanks considerably exceeds those of horizontal tanks designed for land transportation. Under the conditions of normal exploitation, such tanks are loaded mainly with internal pressure being the sum of hydrostatic

pressure and the uniform pressure caused by vapor of the medium contained therein (Magnucki et al. 2004).

For a cylindrical pressure vessel, there are two possible failure modes. One is the maximum stresses reaching the yield condition and then yielding zone spread leading to final plastic collapse and the other is elastic or elastic–plastic buckling leading to collapse. For the first problem it is mainly a stress analysis while for the second problem it is a stability analysis. In particular this instability appears usually in two forms: the elephant foot buckling and the diamond buckling (Niwa and Clough 1982; Haroun and Bhatia 1994; Hamdan 2000). The first form, which is an outward bulge located just above the tank base, results from the combined action of vertical compressive stresses, exceeding the critical stress, and hoop tension close to the yield limit. The second form is an elastic instability phenomenon due to the presence of high axial compressive stresses.

For sake of brevity, this study exclusively deals with stress analysis, while stability analysis is not documented.

More in detail, the present paper analyses the seismic performances of a ground-based horizontal cylindrical tank containing “butane”, focusing on the two topics of sloshing (1) and asynchronous seismic input (2).

As to the first aspect (1), it is worth noting that the seismic analysis of cylindrical storage tanks requires accounting for the fluid–structure interaction. This phenomenon, referred to as “liquid sloshing,” is generated by the presence of a free surface allowing for fluid motions and is generally caused by external tank excitation, significantly affecting in many cases the dynamic response (Hamdan 2000; Patkas and Karamanos 2007).

As to the second aspect (2), asynchronous motion denotes the differences in amplitude, phase and frequency content among ground motions recorded over extended areas (Nuti and Vanzi 2005; Lavorato et al. 2017). This spatio-temporal variation of ground motion is mainly attributed to (Zerva 2009; Koufoudi et al. 2018): (a) difference in arrival times of seismic waves at different locations; (b) loss of coherence of seismic waves (i.e. gradual reduction of its statistical dependence on distance and frequency), due to multiple reflection and refraction as they propagate through the highly inhomogeneous soil medium; (c) ground motion attenuation; (d) impact of local site effects. According to the current Italian and European technical codes (M.I.T 2008, Eurocode 8), if foundations are not properly interconnected with sufficiently rigid elements, asynchronous motion has to be accounted for.

The analysis herein presented comprises a sophisticated numerical FE modeling as well as a simplified model for the estimation of the dynamic properties of the tank structure. The paper is organized as follows: First, the steel cylindrical pressure vessel containing butane adopted for the case study is presented (“Case-study” section). “Sloshing” and “Asynchronous seismic input and resulting structural

demand” sections describe the mathematical model adopted for accounting for the sloshing and the asynchronous seismic input, while “Verification of finite element modeling” section focuses on the fundamental period of the structure. Results of the analyses are given in “Stress analysis” section; finally, conclusions are given in “Conclusions” section.

Case-study

The research focuses on an existing ground-based horizontal cylindrical steel vessel resting upon two r.c. supports through steel saddles and containing pressurized butane (density $\rho_L = 603 \text{ kg/m}^3$). The cylinder is 14.66 m long, with external diameter and thickness equal to 4 m and 12 mm, respectively. The lateral sides of the cylinder are constituted by curvilinear surfaces; a reinforcing steel ring can be observed at the middle of the cylinder (Fig. 2).

The geometrical and mechanical characteristics of the cylindrical vessel are summarized in Tables 1 and 2.

By observing Table 2, it can be noted that a rather low design strength (15 MPa) is attributed to r.c. supports. This choice was made for sake of safety since, in the absence of suitable test survey on the tank under examination, test results on adjacent vessels had highlighted low quality concrete.

Seismic input is given using the acceleration response spectrum defined according to the Italian code (M.I.T 2008). The following design conditions are adopted:

- nominal expected life of the structure: $V_n = 50$ years;
- utilization coefficient of the structure: 4th Class ($C_u = 2$);
- reference period for the seismic action: $V_R = 100$ years;
- behavior factor: $q = 1$.

Seismic zone is identified by the following characteristics: ground type: C; soil type T_1 ($S = 1.5$).

Seismic hazard parameters of the site are given by:

Table 1 Geometrical properties of the cylindrical vessel

External diameter of the cylinder, m	4
Thickness of the cylinder walls, m	0.012
Height of the r.c. supports, m	3.35
Width of the steel saddles, m	3.45
Thickness of the steel saddles, m	0.02

Table 2 Mechanical properties of the cylindrical vessel

Design strength of cylinder steel (f_d) (MPa)	360
Design strength of supporting saddles steel (f_d) (MPa)	230
Design strength of r.c. supports (f_d) (MPa)	15

- design ground acceleration for the no-collapse requirement (ultimate limit state): $a_g = 0.053 \text{ g}$;
- maximum amplification factor of the acceleration response spectrum: $F_0 = 2.571$;
- upper period of the constant acceleration branch of the response spectrum: $T_C^* = 0.512 \text{ s}$.

The above values are representative of low seismicity areas in Italy (Vanzi et al. 2015; Fiorentino et al. 2018).

Sloshing

Seismic design provisions of liquid-storage tanks such as API 650 (2007) and Eurocode 8 (1998) are based on a mechanical spring-mass analogy initially developed by Graham and Rodriguez (1952), Jacobsen (1949) and Housner (1963) for rigid tanks and by Haroun and Housner (1982) for flexible tanks.

According to this analogy, a tank subjected to a seismic motion may be reduced to a simpler model with lumped masses and springs. More precisely a portion of the mass of the liquid content (M_I) is considered as rigidly connected to the tank walls while the remaining portion (M_C) is flexibly attached to the tank walls. The liquid (with mass M_I) that synchronizes with the vibration of the tank is called impulsive while the sloshing component of the fluid (with mass M_C), generating free surface waves and characterized by its own frequency of vibration, is referred to as convective component.

Fig. 1 Mechanical spring-mass analogy of a liquid-storage tank

In this study, the procedure from Karamanos (2004) is adopted to develop the mechanical spring-mass tank model. For broad tanks, the simplified model reported in Fig. 1 can be applied, where the tank-liquid system is represented by the first impulsive and first convective modes only. In fact, numerical calculations of hydrodynamic forces in horizontal cylinders and spheres showed that, in this case, considering only the first mode may provide a very accurate prediction of the convective and impulsive forces.

In Fig. 1, $y_2 = X(t)$ represents the motion of the external source while $y_1 = u_1(t)$ expresses the motion of the liquid mass associated to sloshing.

The total mass M_T is split into two parts m_1 and m_2 , corresponding to y_1 and y_2 and expressing the “convective” or “sloshing” motion (M_{IC}) and “impulsive” motion (M_I), respectively.

As suggested by Eurocode 8 (1998), the seismic design force F_D can be calculated through the SRSS combination of the convective and impulsive maximum values $F_{C,max}$ and $F_{I,max}$:

$$F_D = \sqrt{(F_{C,max})^2 + (F_{I,max})^2} \tag{1}$$

The maximum convective $F_{C,max}$ and impulsive $F_{I,max}$ forces, neglecting the higher modes of vibration, are given by

$$F_{C,max} = M_{IC} S_A(T_{IC}); \quad F_{I,max} = M_I S_A(T_I) \tag{2}$$

where $S_A(T_{IC})$ and $S_A(T_I)$ represent the spectral acceleration calculated in correspondence of the fundamental sloshing and impulsive periods, respectively.

The above quantities can be computed by utilizing the graphs and the tables reported in (Karamanos 2004), which refer to a cylindrical tank belonging to the same typology of the one herein analyzed. The procedure can be so summarized: (1) calculating the liquid mass M_L on the basis of the fluid level in the tank; (2) calculating the total moving mass $M_T = M_L + M_{tank}$, M_{tank} being the mass of the empty tank; (3) deriving the convective mass M_{IC} from Table 2 in (Karamanos 2004); (4) computing the total impulsive mass $M_I = M_T - M_{IC}$; (5) obtaining the fundamental sloshing period T_{IC} and the fundamental impulsive period T_I from Tables 1, 2, 3, 4, and 5 in (Karamanos 2004). In the same Table 5 also the maximum convective force $F_{C,max}$, impulsive force $F_{I,max}$, and the total design force F_D for different liquid levels within the cylinder are reported. It can be noted that, since sloshing is a low-frequency motion, the corresponding spectral values are small and as a consequence, the impulsive component of the

response prevails. Thus the maximum seismic design force, i.e. the most unfavorable condition, is obtained in corresponding of the maximum possible liquid fill height in the cylinder, that is when the fluid mass tends to behave like an impulsive mass and sloshing effects become negligible.

Application to the case study

On the basis of the above considerations, the seismic analysis of the cylindrical tank object of study was carried out under the most unfavorable hypothesis of maximum seismic force, that is with the cylinder filled with butane up to the “block level” (i.e. the maximum allowable liquid level in the tank for safety reasons) equal to 80% in height. The 80% filling height corresponds to the 85% filling volume. Table 3 shows the deriving values of the involved parameters.

From Table 3, by comparing the values of F_D , $F_{C,max}$ and $F_{L,max}$, it can be deduced that the convective component of

the fluid motion is negligible. So dynamic spectral analyses were carried out by modeling the liquid mass through its impulsive component only. In this way, an accuracy higher than 99% was obtained.

Verification of finite element modeling

The fundamental period of the cylindrical tank was determined by adopting two different approaches:

1. a detailed finite element (FE) model;
2. a simplified methodology based on a SDOF analogy.

The structure was assumed perfectly constrained at the basis.

As to the first approach (Resta et al. 2013), the tank was modeled by the FE structural analysis code Midas Gen 2017. Different typologies of FEs were used (Fig. 2): (1) plate elements to model the cylinder walls; (2) solid elements to model the steel saddles and the r.c. supports. A fundamental period equal to 0.2643 s in the x (longitudinal) direction and 0.1376 in the y (transversal) direction was so obtained (Fig. 3).

With regard to the second approach, the vessel was assimilated to a SDOF system with the mass given by the sum of four contributions: the cylinder steel mass; the saddles steel mass; part (1/3) of the mass of r.c. supports; the butane impulsive mass. The overall stiffness was schematized by a parallel-system of springs (Fig. 4). More precisely it was achieved by considering the stiffnesses (k_{st}) of the vertical r.c. supports arranged in parallel. By recalling that the stiffness, k_{eq} , of a parallel system is given by the sum of the different stiffness aliquots, it can be written as follows:

Fig. 2 FE model of the cylindrical tank

Fig. 3 First two modes of vibration of the cylindrical tank

Fig. 4 SDOF analogy of the cylindrical tank

$$T = 2\pi \sqrt{\frac{M_{eq}}{k_{eq}}}; \quad k_{eq} = 2k_{st}; \quad k_{st} = \alpha \frac{EJ}{H^3}. \quad (3)$$

Assuming $\alpha = 3$, a fundamental period in the longitudinal direction equal to 0.254 s was computed, in perfect accordance with the value obtained through the FE model. The values of the various quantities involved in the analysis are summarized in Table 4.

Asynchronous seismic input and resulting structural demand

According to the current Italian code (M.I.T 2008, section 7.2.5.1) and to Eurocode 8, if foundations are not properly interconnected with sufficiently rigid elements, the

effects of relative horizontal displacements at the basis of the superstructure should be analyzed in order to account for possible asynchronous actions.

The cylindrical vessel under examination belongs to this typology and thus the effects of non-synchronism were considered by introducing suitable soil differential displacements in the x and y directions at the foundation base. The differential displacements in the two directions were calculated according to section 3.2.5.2 of Italian code, excerpted from Nuti and Vanzi (2005), so obtaining in both directions $d_{ij}(x) = 7$ mm.

Pseudo-static analyses were first carried out singularly in the x and y directions (Figs. 5, 6), while in a second step soil distortions were introduced simultaneously in the two directions (Fig. 7). In all cases significant high stresses arose in the supporting saddles and in cylinder walls in correspondence of saddles, so highlighting that asynchronous actions can sensibly affect the stress level of the cylindrical tank and cannot be neglected. The maximum Von-Mises stresses obtained by the pseudo-static analyses are summarized in Table 5.

Stress analysis

The stress analysis was performed using the FE model of the cylindrical pressure tank depicted in “Verification of finite element modeling” section. The following load cases were considered:

- dead load (G_1);
- internal pressure ($P_i = 6$ bar);
- hydrostatic pressure (P_H , due to butane);
- seismic spectral loads in all three directions.

Fig. 5 Stress configuration due to soil differential displacements in the x direction (Von-Mises stresses): a cylinder walls; b supporting saddle

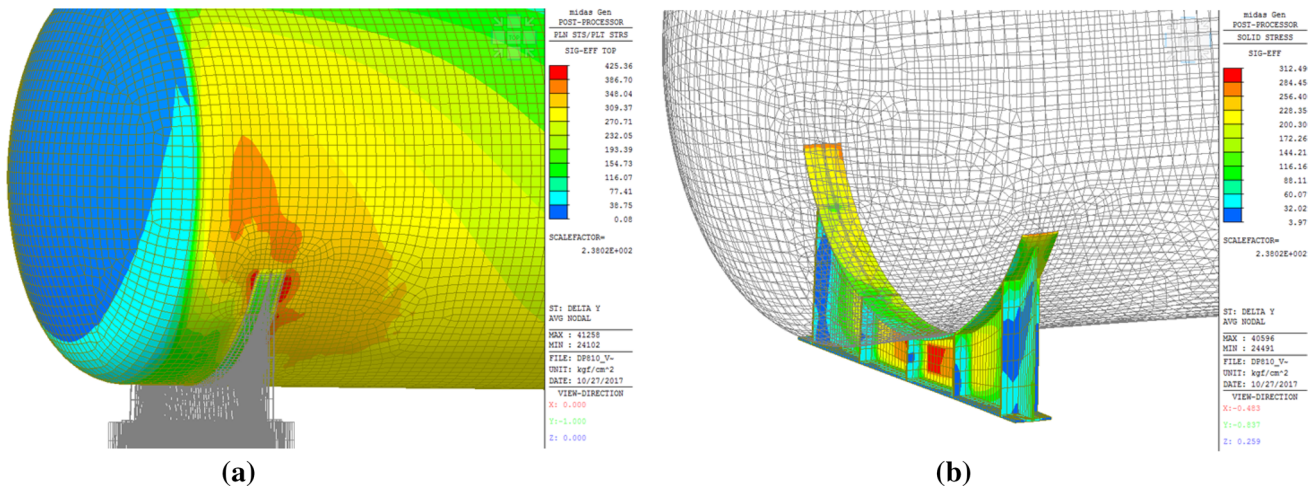

Fig. 6 Stress configuration due to soil differential displacements in the y direction (Von-Mises stresses): a cylinder walls; b supporting saddle

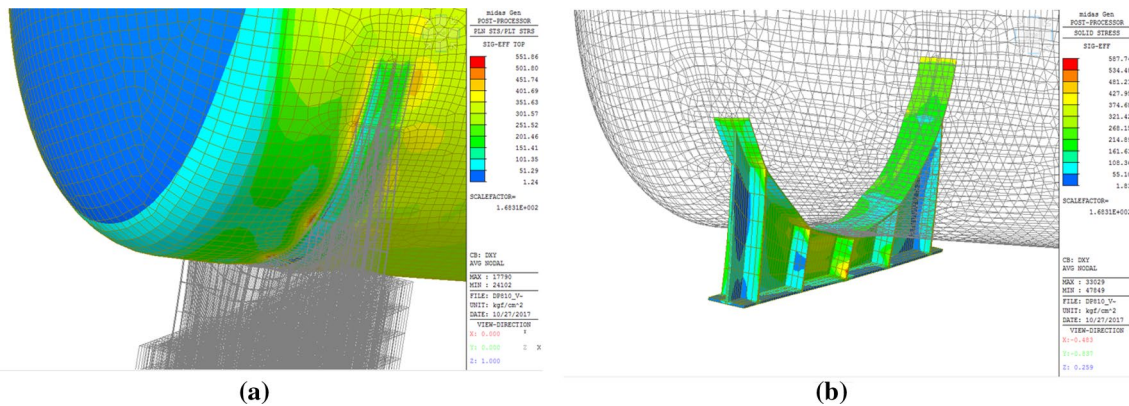

Fig. 7 Stress configuration due to soil differential displacements in both x and y direction (Von-Mises stresses): a cylinder walls; b supporting saddle

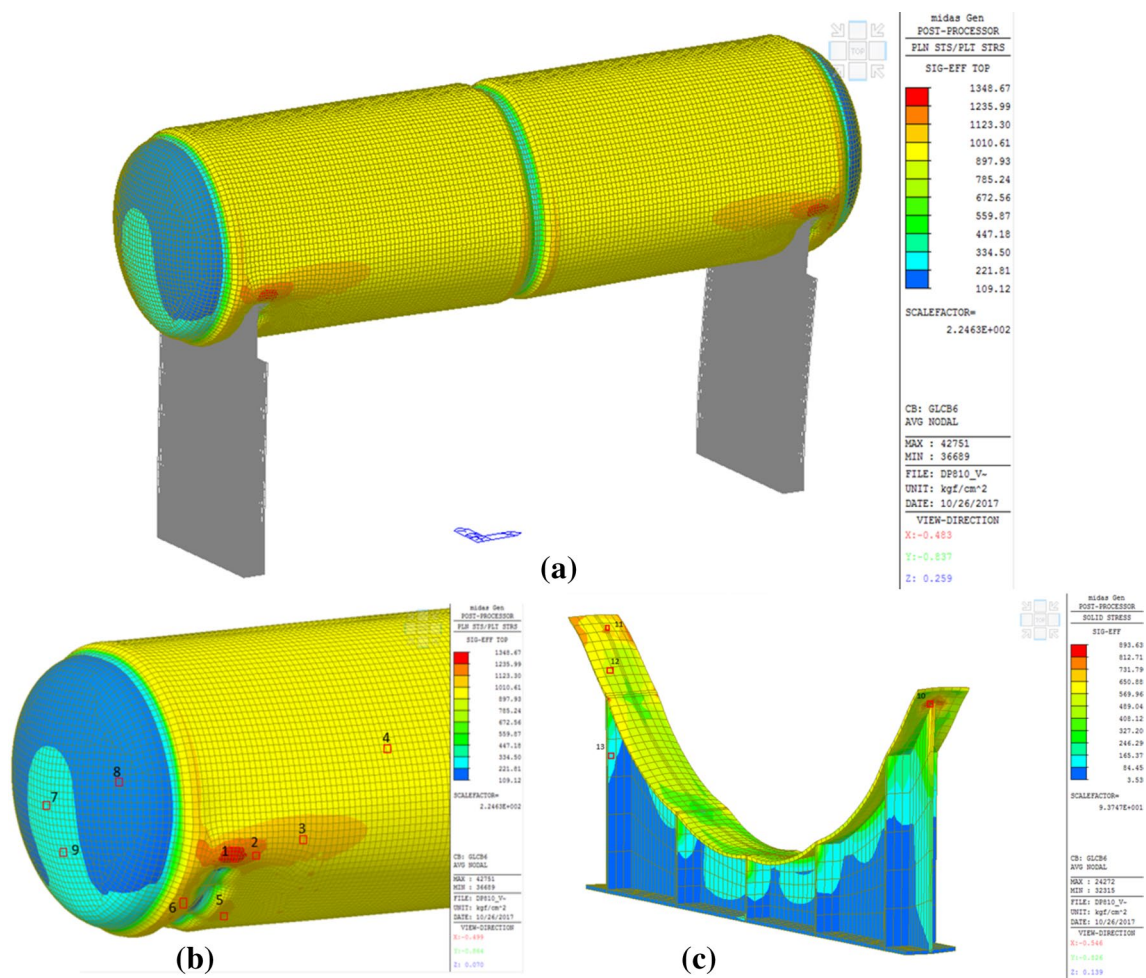

Fig. 8 Stress configuration in correspondence of the most unfavorable seismic load combination (Von-Mises stresses): **a, b** cylinder walls; **c** supporting saddle

Table 6 Stress verifications (Von-Mises stresses; maximum values compared with strength values)

Element	σ_{eff} MPa	f_d MPa	Ratio β	Verification
Cylinder lateral walls	134.3	360	2.68	Satisfied
Cylinder vertical walls	22.8	230	10.09	Satisfied
Supporting saddles	89.4	230	2.57	Satisfied

Verifications were carried out in terms of Von-Mises stresses. The following load combination resulted to be the most unfavorable condition:

$$1 \cdot G_1 + 1 \cdot P_i + 1 \cdot P_H + 0.3 \cdot \text{Seism } X + 1 \cdot \text{Seism } Y + 0.3 \cdot \text{Seism } Z. \tag{4}$$

Figure 8a–c shows the corresponding stress distributions; in particular Fig. 8a, b highlights stresses in the cylinder while Fig. 8c focuses on stresses in supporting saddles. Maximum stress values are reported in Table 6, while Table 7 focuses on stresses in some selected nodes, depicted in Fig. 8b, c. Maximum stresses arise at the interface between supporting saddles

Table 7 Stress verifications in selected FE nodes (in terms of Von-Mises stresses)

Nodes (from Fig. 8)	1	2	3	4	7	8	9	10	11	12	13
σ_{eff} (MPa)	134.3	118.9	105.5	93.4	22.8	20.7	22.6	89.4	78.4	37.5	11.7
f_d (MPa)	360	360	360	360	230	230	230	230	230	230	230
Ratio β	2.68	3.03	3.41	3.85	10.08	11.11	10.17	2.57	2.93	6.13	19.66

and cylinder walls, that is in corresponding of the constraint sections, where, in absence of section increments, a stress increase is reasonable.

As it emerges from Tables 6 to 7, in all elements maximum stresses are lower than the corresponding design limit strengths, that is the analyzed cylindrical tank has a good level of safety against seismic action. Verifications on RC supports are not documented due to the absence of experimental tests on steel reinforcement details. However, it can be argued that they behave like perfectly constrained shelves, mainly stressed in the x direction, and at most the low seismic forces acting on them can lead to the early formation of plastic hinges at the basis, with low ductility involvement (Fiore et al. 2016; Imperatore et al. 2012; Lavorato and Nuti 2010; Lavorato et al. 2015; Zhou et al. 2015).

Displacement diagrams for the same load combination are also given in Fig. 9. Maximum displacements result equal to: 1.99 mm in the x direction; 3.4 mm in the y direction; 1.33 mm in the z direction.

Finally, in order to account for the effects of asynchronous actions, the response of the structure after the application of soil differential displacements (as described in “Asynchronous seismic input and resulting structural demand” section)

was combined with the inertial response. The following seismic combination resulted to be the most unfavorable one:

$$1 \cdot G_1 + 1 \cdot P_1 + 1 \cdot P_H + 0.3 \cdot \text{Seism } X - 1 \cdot \text{Seism } Y + 0.3 \cdot \text{Seism } Z + 1 \cdot \Delta x + 1 \cdot \Delta y. \quad (5)$$

The resulting stress configurations and maximum stresses are reported in Fig. 10 and Table 8 respectively, showing an increment of response with respect to the previous case.

It is worth to note that, when liquid storage tanks are founded on piles, in some cases soil–structure interaction could be beneficial, leading to a higher value of natural period and to reduced seismic spectral forces (Fiore et al. 2018). This effect could so diminish the stress increments due to asynchronous seismic motion.

Conclusions

In this study, the seismic behavior of a cylindrical pressure vessel containing butane was analyzed, accounting for the influence of sloshing effects and of asynchronous actions. Both a detailed FE model of the horizontal cylindrical tank and a simplified SDOF model were implemented. It was

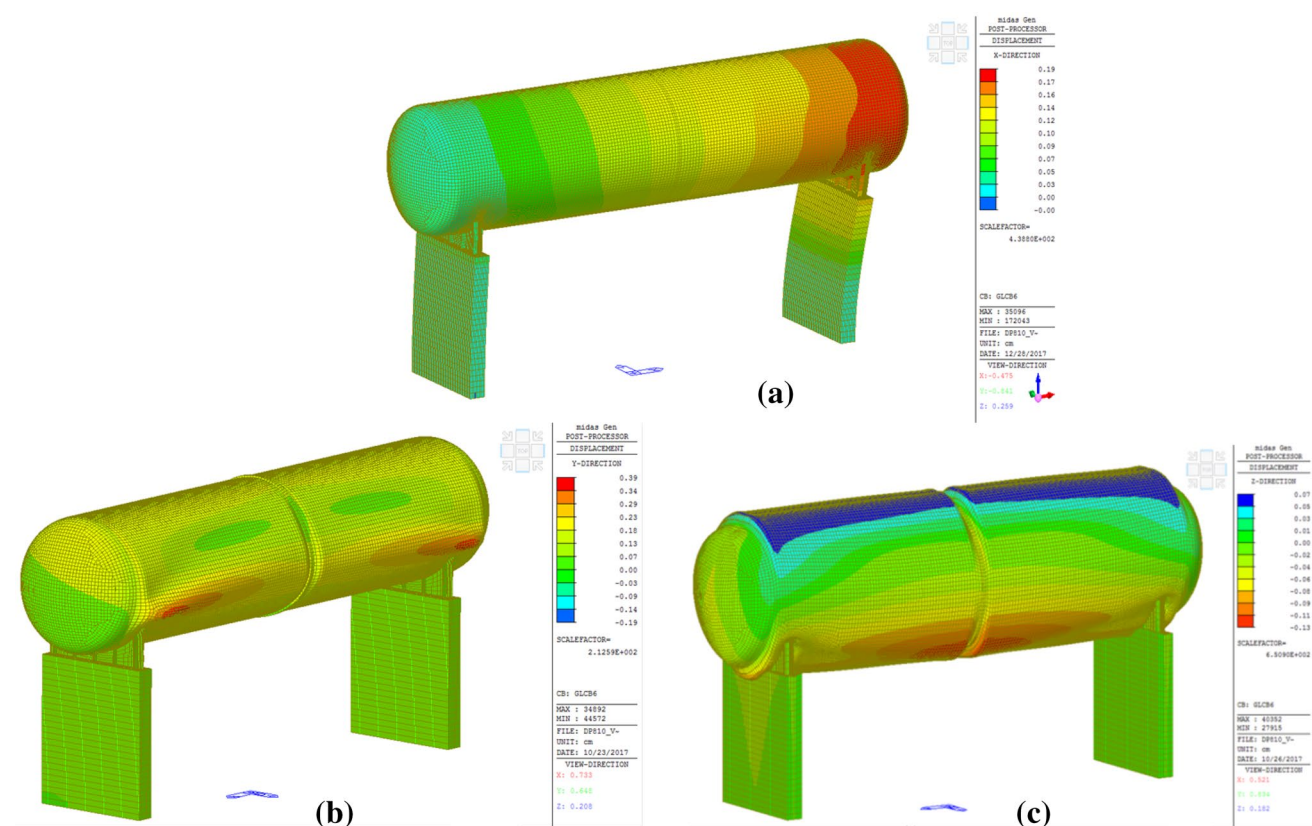

Fig. 9 Resultant displacements for the most unfavorable seismic load combination: **a** x direction; **b** y direction; **c** z direction

Fig. 10 Stress configuration including the effects of asynchronous ground motion (in terms of Von-Mises stresses): **a** cylinder walls; **b** supporting saddle

shown which are the most unfavorable load conditions to be considered under sloshing and asynchronous input effects: (1) seismic action with liquid in the sphere up to the “block level”; (2) non-synchronism of ground motion in both x and y directions.

The high stress level associated with asynchronous seismic action was actually unexpected, given the low seismic design action. This was due to structural peculiarities, in which a very stiff and resistant system (the r.c. column) is connected to the tank via a welded steel saddle, which must accommodate, on a short length, the largest part of differential displacements. However, the possible steel yielding for higher seismic actions would not be a problematic issue for non-pressurized vessels; pressurized vessels, though, require larger reliability margins and simultaneous application of capacity design concepts, in order to satisfy structural safety when verified under large (larger than this paper design earthquake) seismic actions.

For the case of pressurized vessels, this is a reminder to check, even for low seismic action, for structural peculiarities (e.g. constraint behavior; coupling of very and moderately stiff/resistant components), which may become the weakest link for the whole structure, and, once identified, may quite often be structurally upgraded with modest efforts.
