23 Abstract

Damping Reduction Factor plays a key role in scientific literature and Technical Codes, but till now 24 existing formulations present differences and inconsistences probably because obtained by 25 26 integration of real recorded events, thus sensitive to specific used data. This paper investigates the 27 relation between damping reduction factor and earthquake duration by means of random vibration theory. A stochastic process, that is non-stationary and filtered, is used to model a seismic event. The 28 29 modulation function is suitably chosen to describe earthquakes characterized by different durations. 30 The stochastic process peak theory allows to calculate damping reduction factor after the definition of the probabilistic response of a simple linear visco-elastic oscillator. The variability with seismic 31

32 duration for different soil conditions and damping ratios is investigated. The study points out that 33 damping reduction factor is more sensitive to seismic duration in the range of high period and on 34 rigid soil with respect to other conditions. The results show that, if damping ratio or effective duration 35 values are increased, the damping reduction factor value diminishes.

40 **1. Introduction**

41 Serious seismic damage observed on structures and infrastructures systems up to today [1] can be 42 prevented by means of retrofitting interventions if the capacity of these systems and the seismic 43 demand are properly evaluated [2]-[6]. In structural seismic design, Damping Reduction Factor 44 (DRF) represents an effective tool for design purposes to estimate the demand by response spectra 45 characterized also by damping ratios different from 5% as in case of structures equipped with passive 46 energy dissipation or isolation systems. DMF modifies the values of the conventional elastic spectral 47 response with damping ratio equal to 5% to the values corresponding to a different damping level. It 48 is defined as the ratio between the spectral ordinate at 5% of conventional damping and the spectral 49 ordinate at a different level of damping.

50 DRF finds many applications to study the behavior of structures [7], especially for the ones equipped 51 with passive energy dissipation or isolation systems [8]-[12]. In these situations, the DRF permits to 52 estimate the variation of the structural response (displacements and forces) due to the high 53 supplemental damping values [13]-[16]. In addition, for inelastic structures, DRF allows to calculate 54 the maximum displacement demand from the one of an equivalent linear system [8]. For these and 55 other reasons the DRF is particularly suitable for the seismic design of a structure since it provides a 56 practical evaluation of the reduction of earthquake loads for effects of structural, non-structural and 57 supplementary energy dissipation systems. For that reason, it is selected as a key parameter in the 58 present study.

In past years, several studies for the formulation of the DRF have been carried out by many researchers, the outcomes of which have been adopted by the main seismic codes. Different expressions for the DRF can be found in literature. Up to today, the main research efforts have been oriented to the study of the response of a simple (elastic) SDOF system with viscous damping under seismic action [17]-[23]. As a consequence, the codes introduce a DRF that depends on the damping ratio only, whereas different authors [21]-[23] showed that various parameters may affect the DRF. There are two ways to classify the parameters that much influence the DRF: by non-structural

parameters such as earthquake magnitude, ground motion duration (GMD), site conditions, epicentral 66 67 distance, etc. or by structural parameters such as damping of the structure, natural vibration period, 68 dissipation device properties (energy dissipation capacity), etc.. A very interesting topic is represented 69 by the dependence of DRF on seismological parameters. This dependence is much evident 70 considering local site conditions, source distance and magnitude of the earthquake [21]-[24]. In [25] 71 a simulation procedure to estimate the DRF based on an artificial neural network has been developed. 72 The effect of magnitude on the DRF is greater in case of large earthquakes as it was pointed out in 73 different studies [22] for structures with natural periods greater than 0.5 sec. Attention should be 74 placed in case of structures with shorter natural periods (< 0.5 sec) for which the magnitude can have 75 also contrary effects [23]. Concerning the influence of seismological parameters on DRF, Bommer 76 et al. [22] focused their studies on the GMD. The authors observed that it is possible to take into 77 account the influence of magnitude and distance by studying the effect of the GMD and the number 78 of cycles. Based on this observation, Stafford et al. [26] introduced significant equations that give the 79 DRF for different damping ratios starting from the number of cycles and the GMD. In its research, 80 Stafford concluded that a prediction model based on the GMD parameter could be used with 81 difficulties as this parameter usually is not one of the parameters elaborated and directly available in 82 earthquakes database. However, non - distinction between soil types is given by Stafford et al. [26]. 83 Rosenblueth [27] suggested an equation to predict the influence of GMD on DRF and, in accordance 84 with Stafford et al. [26], concluded that the influence of GMD appears negligible for earthquake 85 GMD larger than about 20 sec.

The GMD finds a different definition in the models proposed by Stafford et al. [26] and Rosenblueth [27] but a very good match is observed for damping ratio equal to 10%. Some discrepancies are noticeable among the two models when damping ratio increases. The influence of GMD on DRF has been also investigated by Anbazhagan et al. [28]. The authors choose the pseudo-spectral acceleration to define the DRF and investigate how the DRF varies as a function of magnitude and GMD, distance of earthquake hypocenter, classification of site (soil type), period and damping. The dependence of DRF on the GMD was also analyzed by Daneshvar et al. [29] which concluded that DRF mainly

93 depends on the GMD and the frequency content that are different for each record. Zhou et al. [30] 94 studied how the DRF is affected by the effective GMD. The authors point out that greater values of 95 the damping ratio or of the effective GMD produce smaller values of DRF. However, the GMD is 96 function of distance and magnitude of ground motion and of soil type, that are parameters much more 97 common and available in ground motion database. For that reason, it is usually preferable to define a 98 function between these parameters and the DRF that indicates also a relation between DRF and GMD. 99 However, in this study the authors do not include the type of soil in the evaluation of dependence of 100 DRF with GMD.

101 Rezaeian et al. [31] propose a model to relate the DRF to the magnitude and distance to include in 102 the model the high influence of GMD. The influence of different parameters on DRF is not the same 103 in the cited studies because the sites are classified in different way and the selection of ground motions 104 is performed by different criteria. So a stochastic process is adopted in the proposed study to 105 overcome this difficulties.

106 In a previous study [32] the authors, by means of the random theory approach, investigated the effect 107 of soil type on DRF and demonstrated that not only the predominant frequency of the seismic event 108 but also the bandwidth of seismic signal affect the DRF. Since the study of the joint effect on DRF 109 of parameters such as soil type and GMD has not performed in other studies, the authors will develop 110 random vibration theory to analyse in a combined way the influence of earthquake duration and soil 111 type on DRF. GMD is a key parameter in seismic design. Since the 1950s, the peak acceleration, 112 frequency content and GMD are considered important parameters to design the structures but up to 113 today the peak acceleration and frequency content are the only parameters used in design methods. 114 The influence of GMD on DRF is investigated in the present study by means of the random vibration 115 theory: a modulated filtered stochastic process is applied on a linear single degree of freedom (SDF) 116 system and the peak theory of stochastic process is used to calculate the seismic spectrum in stochastic 117 terms. The product of a time modulation function [33] [34] and a stationary filtered stochastic process 118 gives a modulated non-stationary stochastic process. A series of two linear oscillators forced by a 119 modulated white noise process permit to obtain the linear fourth order filter that is adopted in the 120 procedure. A formulation correlating the modulating function and the GMD through the Arias intensity [42] is introduced to analyze the effects of the GMD on DRF. In this way, the stochastic dynamic response can be evaluated for different GMDs, properly defining the modulation function and therefore a sensitivity analysis on DRF can be carried out to evaluate how DRF changes as a function of different parameters. The proposed approach overcomes the limitations of the strategies based on seismic records of real events, because in these it is difficult to accurately identify the influence of different factors. This is pointed out by discrepancies between the various studies existing in the literature.

The main advantage of using a stochastic approach is, on the contrary, the possibility to represent seismic motion by a simple model defined by few parameters, but able to describe the most seismological characteristics of real earthquakes as content of energy, frequency and GMD. On the other hand, the proposed approach would require an assessment of the spectrum parameters themselves on the basis of seismic models that are more consistent with the seismic scenario.

The study is presented in the following sections: the stochastic model of the seismic acceleration is explained in section 2. The relation between the modulation function parameters and GMD is defined in section 3. The evaluation of DRF in stochastic terms is developed in section 4. The results of the sensitivity analysis developed considering different GMDs and soil conditions are shown and then discussed in section 5. A formulation for DRF evaluation useful for practical applications is proposed and compared with other existing formulations in section 6. Finally, the conclusions are given in section 7.

140

2. Stochastic Modelling of Seismic Motion

Seismic acceleration is assumed as a uniformly modulated non-stationary stochastic process that is calculated by the product of a time modulation function $\varphi(t)$ and a stationary process [35]. The stationary part of the process is described by the well known filtered process proposed by Clough et al. [36]: two linear oscillators in series, subjected to a modulated white noise process give a linear fourth order filter. Ground acceleration \ddot{X}_g is given by:

146
$$\begin{cases} \ddot{X}_{g}(t) = -\omega_{p}^{2}X_{p}(t) - 2\xi_{p}\omega_{p}\dot{X}_{p}(t) + \omega_{f}^{2}X_{f} + 2\xi_{f}\omega_{f}\dot{X}_{f}(t) \\ \ddot{X}_{p}(t) + \omega_{p}^{2}X_{p}(t) + 2\xi_{p}\omega_{p}\dot{X}_{p}(t) = \omega_{f}^{2}X_{f} + 2\xi_{f}\omega_{f}\dot{X}_{f}(t) \\ \ddot{X}_{f}(t) + 2\xi_{f}\omega_{f}\dot{X}_{f}(t) + \omega_{f}^{2}X_{f} = -\phi(t)W(t) \end{cases}$$
(1)

147 where W(t) is the white noise stochastic process, with Power Spectral Density function S_0 ; $X_f(t)$ is 148 the first filter response, with frequency ω_f and damping ratio ξ_f , $X_p(t)$ is the second filter response 149 with frequency ω_p and damping ratio ξ_p ; $\phi(t)$ is the modulation function. The present research 150 assumes the Jennings' modulation function [37], below reported:

151
$$\phi(t) = \alpha t e^{-\beta t} \quad \alpha, \beta > 0 \tag{2}$$

152 α , β being the parameters that describe the shape of the modulation function that will be selected in 153 section 3.

3. Definition of modulation function considering the earthquake duration

Until now, GMD has been defined in different ways in literature [38] but the bracketed duration, the 155 uniform duration and the significant duration are the most used. For a given curve that shows the 156 157 values of the acceleration as a function of the time, the duration of the ground motion is a time 158 interval. In the case of bracketed duration, a threshold value of acceleration (usually 0.05 g) is defined. 159 The bracketed duration [39] is the time interval between the time corresponding to the first and the 160 time corresponding to the last overrun of the defined threshold value of acceleration. The choice of 161 the threshold value is different in literature and therefore this definition of GMD results subjective (it can be absolute or relative e.g. 10% of Peak Ground Acceleration (PGA)). The uniform duration [40], 162 [41] is calculated as the sum of time intervals. During each time interval the acceleration values 163 164 overrun the threshold value of the acceleration. This definition of GMD is explained in a way similar 165 to the bracketed duration except for the interval between the thresholds. The disadvantages in the use 166 of this GMD definition are: the dependence of the GDM on the chosen threshold acceleration value; 167 the influence of small earthquakes recorded before or after the main earthquake record that could be 168 included in the GMD evaluation. The effective duration is a preferable definition of GMD because it 169 is the time interval necessary to release a given seismic energy content. The Arias intensity I_a [42] 170 that considers the integral square of the ground acceleration, a measure of the energy content, is 171 usually chosen to define this GDM. The Arias intensity is defined as:

172
$$I_a = \frac{\pi}{2g} \int_0^{T_t} \ddot{x}_g^2(t) dt$$
(3)

where $\ddot{x}_{g}(t)$ is the time history of the ground acceleration, *g* is the acceleration of gravity and T_{t} is the GMD of the record. The time intervals T₅₋₇₅ and T₅₋₉₅ between 5%-75% and 5%-95% of the Arias intensity (I_a) are respectively the two measures of significant duration most used in literature.

In this study, in order to analyze the influence of GMD on DRF, T₅₋₉₅ is considered, as it is one of the most common measure of GMD and it can be related to magnitude, distance and soil type. Different empirical formulation have been proposed in literature for effective duration [43]-[46] which consider the dependence on magnitude, distance and soil condition. The outcome was that effective duration increases with distance, magnitude and moving from rock to soft soil. Among these three influencing parameters, soil type has a larger influence than distance.

The present research deals with the evaluation of the influence of the effective duration on DRF for 182 183 different soil conditions. To develop a suitable model for this analysis, a formulation correlating the 184 modulating function and T₅₋₉₅ (effective duration) throughout the mean value of I_a is obtained. In this 185 way, stochastic dynamic response can be evaluated for different GMDs, properly defining the 186 modulation function. In order to achieve the correlation between GMD and modulation function, the 187 two parameters α and β in Eq. 2 are obtained by an identification procedure. Introducing the time t_m where the modulation function exhibits its maximum value, parameters α and β are expressed 188 as functions of this unknown parameter from the simultaneous equations: 189

190
$$\begin{cases} \phi(t_m) = 1\\ \frac{d}{dt}\phi(t_m) = 0 \end{cases}$$
(4)

191 The two parameters α and β are then evaluated as function of t_m :

$$192 \qquad \beta = \frac{1}{t_m} \tag{5}$$

193
$$\alpha = \frac{e}{t_m} \tag{6}$$

194 The dimensionless time ratio $\tau = \frac{T_t}{t_m}$ can be introduced in Eq. (2), so obtaining:

195
$$\phi(\tau) = \tau e^{(1-\tau)} \tag{7}$$

196 197

Figure 1: Modulation function (Φ) *in dimensionless time* (τ)

198 The time values at which 5 % and 95 % of the Arias intensity is reached can be used to evaluate the 199 effective duration T_{5-95} . In stochastic terms, the mean value of I_a could be evaluated as:

200
$$\mu[I_a] = \frac{\pi}{2g} \int_0^{T_t} \langle \ddot{x}_g^2(t) \rangle dt = \frac{\pi}{2g} \sigma_{\ddot{x}_g}^2 \psi_a(T_t)$$
(8)

where T_t is the total duration of the acceleration record, $\sigma_{\ddot{x}_g}^2$ is the variance calculated for the acceleration of the ground, $\langle \ddot{x}_g^2(t) \rangle$ denotes the expected value of the square of \ddot{x}_g and $\psi_a(T_t)$ is defined by:

204
$$\psi_a(T_t) = \int_0^{T_t} \phi^2(t) dt$$
 (9)

205 Now using Eq. (7), Eq. (9) becomes:

206
$$\int_{0}^{\rho} \phi(\tau)^{2} d\tau = \frac{1}{4} e^{2} \left(1 - e^{-2\rho} \left(1 + 2\rho \left(1 + \rho \right) \right) \right)$$
(10)

207 where
$$\rho = \frac{T}{t_m}$$
. At the end of the phenomenon ($T = \infty$), it results:

$$208 \qquad \psi_a(\infty) = \int_0^\infty \phi(\tau)^2 d\tau = \frac{e^2}{4} \tag{11}$$

So the dimensionless time ρ_k necessary to release the k% of the total I_a is the solution of the following equation:

211
$$\int_{0}^{\rho_{k}} \varphi(\tau)^{2} d\tau = k \int_{0}^{\infty} \varphi(\tau)^{2} d\tau$$
(12)

that means in implicit form:

213
$$\frac{1}{4}e^{2}\left(1-k-e^{-2\rho_{k}}\left(1+2\rho_{k}\left(1+\rho_{k}\right)\right)\right)=0$$
(13)

Equation (12) allows the definition of the ρ_5 and ρ_{95} values corresponding to the 5% and the 95% of

215 the energy I_a calculated on the modulation function respectively. The values so obtained are:

216
$$\rho_5 = 0.40884 \\ \rho_{95} = 3.1478$$
(14)

217 Thus the values t_m corresponding to the selected effective duration T_{5-95} can be determined by the 218 definition of the ratio ρ :

219
$$T_5 = 0.40884t_m T_{95} = 3.1478t_m$$
 (15)

Finally, the effective duration is $T_{5-95} = 2.7390t_m$, so that it is possible to define t_m as:

221
$$t_m = \frac{T_{5-95}}{2.7390}$$
 (16)

4. Evaluation of Damping Reduction Factor by peak theory

226 In this section, the seismic ground acceleration action $\ddot{X}_{e}(t)$ given by Eq. (1) is applied on a simple 227 linear-viscous SDOF system to evaluate the DRF in stochastic meaning. For this system, the motion equation is: 228

229
$$\ddot{X}_{s}(t) + 2\xi\omega\dot{X}_{s}(t) + \omega^{2}X_{s}(t) = -\ddot{X}_{g}(t)$$
 (17)

where X_s is system-ground relative displacement, ω is the natural frequency and ξ is the damping 230 231 ratio:

232
$$\omega = \sqrt{\frac{k}{m}} \text{ and } \xi = \frac{c}{2\sqrt{km}},$$
 (18)

233 *k* and *m* being the system mass and stiffness, respectively.

234 In the state-space, the motion equation of the system becomes:

235
$$\mathbf{Z}(t) = \mathbf{A}\mathbf{Z}(t) + \mathbf{F}(t).$$
(19)

236 where \mathbf{F} is the force vector and \mathbf{Z} is the state-space vector:

237
$$\mathbf{Z} = \left(X_s, X_p, X_f, \dot{X}_s, \dot{X}_p, \dot{X}_f\right)^T$$
(20)

238
$$\mathbf{F} = (0, 0, 0, 0, 0, -\varphi(t) w(t))^{T}$$
 (21)

239 Finally **A** is the state matrix:

240
$$\mathbf{A} = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ -\omega^2 & \omega_p^2 & -\omega_f^2 & -2\xi \,\omega + 2\omega_p \xi_p & -2\omega_f \xi_f \\ 0 & -\omega_p^2 & +\omega_f^2 & 0 & -2\omega_p \xi_p & +2\omega_f \xi_f \\ 0 & 0 & -\omega_f^2 & 0 & 0 & -2\omega_f \xi_f \end{pmatrix}$$
(22)

The matrix Lyapunov differential equation [47]-[54] can be used to calculate the stochastic response of the system when it is excited by the non-stationary modulated Clough and Penzien stochastic process:

244
$$\mathbf{\hat{R}}(t) = \mathbf{A}\mathbf{R}(t) + \mathbf{R}(t)\mathbf{A}^{T} + \mathbf{B}(t)$$
 (23)

245 where $\mathbf{R}(t) = \langle \mathbf{Z}\mathbf{Z}^T \rangle$ is the covariance matrix and $\mathbf{B}(t)$ is a matrix that is square and has all elements

equal to zero except for the last one that assumes the value $2\pi S_0 \phi(t)^2$.

247 For the analyzed system, a definition of the displacement spectrum is:

$$248 \qquad S_d = \left| X_s(t) \right|_{max} \tag{24}$$

249 The DRF (η) parameter permits to approximate the high damped elastic response spectrum (S_d)

250 starting from the 5% damped one ($S_{d,\xi=5\%}$):

$$251 \qquad S_d = \eta S_{d,\xi=5\%} \tag{25}$$

where ξ is the damping ratio that is greater than 5% for the high damped system.

A seismic response spectrum gives the maximum displacement or acceleration response of a SDOF system when a recorded earthquake [4], [6], 5[55][61] is applied as a function of the natural period of the system. Different relations are obtained for different values of structural damping. From a stochastic point of view, the response spectrum is still a relation between the maximum acceleration or displacement response of a SDOF system, that is subjected to a ground motion, and the natural period of the SDOF system but the maximum response and the ground motion are considered in stochastic terms. Different values of structural damping again give different response spectra. 260 In the present paper the authors propose a procedure to calculate the DRF value starting from the definition of the stochastic displacement spectrum by mean of the peak theory. This theory assumes 261 that the maximum response of a SDOF system in displacement X_s^{max} is the displacement value that 262 is not overrun with a fixed value of the probability P_{f}^{*} . For this reason the analysis focuses on the 263 evaluation of this maximum displacement that, from a mathematical formulation, is the displacement 264 threshold b that will not be exceeded with a probability P_{f}^{*} during the system lifetime [62]. If this 265 problem is analyzed for a generic process X and for a threshold b, the Vanmarcke formula [63] gives 266 the probability that the process *X* exceeds the threshold *b*: 267

268
$$P(t,b) = 1 - \exp\left(-\int_{0}^{t} \alpha(\tau)d\tau\right)$$
(26)

269 where the expected decay rate $\alpha(\tau)$ is:

270
$$\alpha(\tau) = v_{X}(b,t) \frac{1 - \exp\left[-\frac{v_{R}^{+}(b,t)}{v_{X}(b,t)}\right]}{1 - \frac{v_{X}^{+}(b,t)}{v_{X}^{+}(0,t)}}$$
(27)

271 $v_x(b,t) = v_x^+(b,t) + v_x^-(b,t)$ being the expected rate of the response that exceeds the threshold. The 272 up and down crossing expected rates are given by [64]:

274 where $f_{XX}(t,b;t,\dot{x})$ is the joint probability density function (JPDF) of X and \dot{X} .

In Eq. (14) the expected up-crossing rate of the envelope process R(t) is indicated with $v_R^+(b,t)$ and R(t) can be expressed as:

277
$$R(t) = \sqrt{X(t) + \hat{X}^{2}(t)}$$
(29)

278 where $\hat{X}(t)$ is the Hilbert transform of X(t).

In Eq. (27) $v_R^+(b,t)$ is obtained from Eq. (15) replacing \dot{x} and $f_{X\dot{X}}(t,b;t,\dot{x})$ with \dot{r} and $f_{R\dot{R}}(t,r;t,\dot{r})$ respectively if the JPDF $f_{R\dot{R}}(t,r;t,\dot{r})$ is available.

For convenience, the above crossing rates are evaluated in a normalized way by introducing the normalized variables:

283
$$Y(t) = \frac{X(t)}{\sigma_x(t)}$$
(30)

285 $\sigma_x(t)$ being the standard deviation of X process and $\hat{Y}(t)$ the Hilbert transform of Y(t).

286 Since $\hat{Y}(t)$ and Y(t) result uncorrelated, Eqs. (15) become:

287
$$v_{X}^{+}(t,b) = v_{Y}^{+}(t,\kappa) = \omega_{0}\phi(\kappa) \left[\phi\left(\frac{\dot{\kappa}}{\omega_{0}}\right) - \frac{\dot{\kappa}}{\omega_{0}} \Phi\left(-\frac{\dot{\kappa}}{\omega_{0}}\right) \right]$$
(32)

288
$$v_{X}^{-}(t,b) = v_{Y}^{-}(t,\kappa) = \omega_{0}\phi(\kappa) \left[\phi\left(\frac{\dot{\kappa}}{\omega_{0}}\right) + \frac{\dot{\kappa}}{\omega_{0}} \Phi\left(-\frac{\dot{\kappa}}{\omega_{0}}\right) \right]$$
(33)

289 where ϕ is the standard normal density function, Φ is the standard normal distribution function and 290 ω_0 is the standard deviation of $\dot{Y}(t)$, given by:

$$\omega_{0}^{2} = E\left[\dot{Y}^{2}(t)\right] = E\left[\frac{\sigma_{X}(t)\dot{X}(t) - X(t)\dot{\sigma}_{X}(t)}{\sigma_{X}^{2}(t)}\right]$$

$$= \frac{\sigma_{\dot{X}}(t)}{\sigma_{X}^{2}(t)} - 2\frac{\dot{\sigma}_{X}(t)}{\sigma_{X}^{3}(t)}c_{X\dot{X}}(t) + \frac{\dot{\sigma}_{X}^{2}(t)}{\sigma_{X}^{2}(t)}$$
(34)

292 The functions Q(t) and $\dot{Q}(t)$ are mutually independent in the case of a normal process, with the 293 Rayleigh and normal distribution respectively given by:

294
$$f_{\varrho}(q) = q \exp\left(-\frac{q^2}{2}\right)$$
(35)

295
$$f_{\dot{Q}}(\dot{q}) = \frac{2}{\sqrt{2\pi \left(\omega_0^2 - \lambda^2\right)}} \exp\left(-\frac{1}{2}\frac{\dot{q}^2}{\left(\omega_0^2 - \lambda^2\right)}\right)$$
(36)

296 where $\lambda(t)$ is the covariance of Y(t) and $\dot{\hat{Y}}(t)$. Since X(t) and $\hat{X}(t)$ are uncorrelated, $\hat{X}(t)$ and $\dot{\hat{X}}(t)$ 297 are uncorrelated too. Starting from the above equations, it is simple to introduce the relation:

298
$$\lambda(t) = E\left[Y(t)\dot{\hat{Y}}(t)\right] = E\left[\frac{X(t)}{\sigma_{X}(t)}\frac{\sigma_{X}(t)\dot{\hat{X}}(t) - \hat{X}(t)\dot{\sigma}_{X}(t)}{\sigma_{X}^{2}(t)}\right] = \frac{c_{X\dot{X}}(t)}{\sigma_{X}^{2}(t)}$$
(37)

299 Then the evaluation of the up-crossing rate for the envelope is possible by:

$$\upsilon_{R}^{+}(t,b) = \upsilon_{Q}^{+}(t,\kappa) = f_{Q}(\kappa) \int_{\dot{\eta}}^{\infty} (s-\dot{\kappa}) f_{\dot{Q}}(s) ds = \sqrt{\omega_{0}^{2} - \lambda^{2}} \kappa e^{-\frac{\kappa^{2}}{2}} \left[\phi \left(\frac{\dot{\kappa}}{\sqrt{\omega_{0}^{2} - \lambda^{2}}}\right) - \frac{\dot{\kappa}}{\sqrt{\omega_{0}^{2} - \lambda^{2}}} \Phi \left(-\frac{\dot{\kappa}}{\sqrt{\omega_{0}^{2} - \lambda^{2}}}\right) \right]$$
(38)

300

301 If $\sigma_{X}^{2}(t)$, $\sigma_{XX}^{2}(t)$, $c_{XX}(t)$ and $c_{XX}(t)$ are available, then the crossing rates of X(t) and R(t) can be 302 evaluated directly. The variation of the natural period of the SDOF allows to calculate the 303 displacement spectrum. $X_{max}^{P^{*}}(t)$ is the maximum displacement such that the probability that X(t) will 304 exceed the domain $[-X_{max}^{P}, +X_{max}^{P}]$ is equal to a given value P^{*} . This inverse problem can be solved 305 by a numerical approach as described in [62].

5. Analysis results

In this section, a sensitivity analysis on DRF is carried out considering the effect of natural period, damping ratio, soil type and effective duration. More in details, different effective durations are considered, and modulation function parameters are identified by the procedure described in section 4. A wide range of GMD is considered, in order to cover all possible earthquakes. Different soil conditions are analyzed (soft, medium and rigid) by assigning the Clough and Penzien model parameters as reported in Table 1. In the analysis it is assumed $P^* = 10^{-3}$.

Medium	10	0.4	1	0.6
Soft	5	0.2	0.5	0.6

Table 1 Filter parameters for different soil types

320 Figures 3 - 5 show the variability of DRF (η) for different soil conditions versus the system natural period $T_0 = 2\pi / \omega$. Each plot corresponds to an assigned value of the system damping ratio ξ . Six 321 values of ξ are considered: 0.10, 0.15, 0.20, 0.40, 0.60 and 0.80. Vertical line defines the ground 322 motion predominant period $T_f = 2\pi / \omega_f$. Figure 3 shows the results for a soft soil. Different colored 323 324 lines correspond to different values of the effective duration T_{5-95} , which varies in the range 10.94s -54.80s. The dependences between the parameters damping ratio, structural vibration period, soil type 325 326 and GMD are represented by means of the plots in Figures 3 - 5. The DRF shows a period-dependent 327 nature in Figure 3. It is worth noting that all curves show the same variability as T_0 varies and moves 328 downwards and as the damping ratio increases in the considered range. The lowest values of DRF 329 occurs when the natural period T_0 equals the predominant period of earthquake T_f . In detail, for T_0 330 $< T_f$ the DRF decreases with the increase of T₀ and reaches a minimum in T_f . Then, for $T_0 > T_f$ the 331 DRF increases with the increase of the natural period T₀. The DRF tends to assume a unity value in 332 correspondence of the lowest or highest values of period. This can be explained by the fact that the 333 forces can be independent from the damping ratio in a very stiff or very flexible structure. It also 334 emerges that DRF value decreases as damping ratio ξ increases. These results have been observed by 335 Zhou et al. [30]. In addition, when period changes the DRF variation seems lower for low damping 336 ratio. For example for $\xi = 0.1$ (Figure 3), DRF varies between 0.84 and 0.64 (for a GMD of 54.8 s), whereas for $\xi = 0.8$, DRF varies between 0.57 and 0.12 (for a GMD of 54.8 s). 337

With regard to the variability of DRF with GMD, that is the main topic of this study, two different considerations can be carried out: firstly, it is noticed that as the GMD increases, the DRF decreases and the plots move downwards. This variability of DRF with GMD is in agreement with the studies from Bommer et al. [22] and Zhou et al. [30]. These authors observed a decrease of DRF when GMD increase. In addition, results show a larger variability of DRF with GMD in the range of high natural periods. The results of these studies make evident that the GMD has important effects on DRF and this should be considered in engineering implications. Secondly, the influence of earthquake GMD depends on damping ratio and it seems larger for the system with lower damping ratio and tends to reduce as the damping ratio increases. Later we will see that this is not always true.

347 Figures 4 and 5 show the results of the sensitivity analysis for medium and rigid soils. Firstly, it is observed that the soil type affects the DRF and more precisely DRF is larger for soft soil. This result 348 349 agrees with the ones presented by Lin et al. [20]: the soil type has a significant effect on DRF 350 especially for very stiff and rock sites. The aspects related to the influence of soil type on DRF have been discussed in a previous study by the authors to which reference is made [32]. With regard to the 351 352 variability of DRF with earthquake effective duration that is the topic of this study, the same 353 variability of the DRF, already observed in the case of soft soil, is observed for medium and rigid 354 soils when GMD varies.

355

Figure 3 Variability of DRF (η) with system natural period (T_0) for soft soil. The ground motion predominant period (T_f) is the blue line.

362 Figure 5 Variability of DRF (η) with system natural period (T₀) for rigid soil. The ground motion predominant period (T_f) is the blue 363 line. 364 Moreover, the dependency of DRF on effective duration is more evident in these two cases with respect to soft soil. Also for medium and rigid soil it is observed that the variability of DRF is more 365 evident for small values of structural damping ($\xi = 0.10 - 0.20$) while tends to be negligible for 366

367 greater values.

To better analyze the influence of natural period and damping ratio on the variation of DRF as a 368 function of the effective duration, it is useful to analyze Figs. 6 - 8, representing the DRF (η) versus 369 370 where the effective duration (T₅₋₉₅). Different colored lines correspond to different values of system 371 damping ratio (ξ); the 4 sub-figures correspond to different system natural periods T_0 ($T_0=0.5$ sec, $T_0=1 \text{ sec}, T_0=1.5 \text{ sec}, T_0=2 \text{ sec}).$ 372

373 Firstly, the case of soft soil is analyzed. It is observed that earthquake GMD does not affect the DRF 374 for system with low natural period ($T_0=0.5$ sec), except for earthquakes with a very short duration. If an exception is made for the curve corresponding to the lowest value of the damping ratio $\xi = 0.10$, 375 376 the curves are practically horizontal. When the natural periods of the system increase, a greater 377 influence of the GMD on the DRF is observed, even for high values of damping ratio. The largest 378 effects of the GMDs are for the system with natural period T=2 sec. In this case, the DRF varies between 0.82 and 0.72 (values evaluated for $\xi = 0.10$). This variability is important since it leads to 379 380 a 12% reduction of the spectral response and the implication in practical engineering applications are 381 relevant. As before mentioned, a greater GMD value means a greater time window in which the 382 seismic recording is analyzed. If the GMD increases, the number of cycles of the seismic event 383 increases and so also damping effects on the response of the system increase. Consequently this 384 produces [65] the decrease of DRF value. By observing in detail plots in Figs 6-8, one can observe 385 that DRF variation with GMD is significant in the initial part and then it reaches gradually a steady 386 state. Generally, it is observed that for a GMD greater than 20 sec the GMD of the excitation does 387 not affect DRF. This result agrees with Stafford et al. [66]. This outcome is also consistent with the 388 conclusions from Zhou et al [30]. The authors concluded that the maximum displacement curve shows 389 a plateau without increasing further in the case of a system on which a higher number of cycles is 390 applied. This study is based on the analysis of the harmonic excitation of SDOF and the results show 391 that DRF is almost constant for each damping value. In addition, it is observed that, at all damping 392 ratio values, the variation trends of DRF with the effective duration are consistent with each other. 393 The greatest variability of DRF is observed for $T_0=2$ sec. The same considerations can be made by 394 observing the graphs in Figs 7 and 8, which refer to a medium and rigid soil, respectively. As already 395 mentioned, for this last type of soil the greater variability of DRF with the earthquake GMD can be

396 observed.

Figure 6 Variability of DRF (η) with earthquake effective duration (T₅₋₉₅) for soft soil; T₀ is the system natural period.

402 Figure 7 Variability of DRF (η) with earthquake effective duration (T₅₋₉₅) for medium soil; T₀ is the system natural period.

Figure 8 Variability of DRF (η) with earthquake effective duration (T₅₋₉₅) for rigid soil; T₀ is the system natural period.

407 In order to evaluate the amount of the DRF variation with GMD and therefore the engineering 408 implications, in Figs 9 - 11 the maximum variability of DRF ($\Delta(\eta)$), that is the DRF value evaluated for the lower effective duration minus the DRF value evaluated for the larger effective duration, is 409 410 shown. All soil conditions are considered. From Fig. 9 (soft soil), it can be firstly observed that the 411 influence of the effective duration on DRF is more relevant in the range of high periods. The 412 maximum variation equal to 0.11 is for T₀=2 s and ξ =0.15. For T₀=0.5 sec the variability of DRF 413 with effective duration always decreases as the damping ratio increases, whereas as the system 414 becomes more deformable a different behavior can be observed. In fact, as the damping ratio increases 415 the effect of effective duration on DRF firstly increases and then decreases as the damping ratio grows 416 up. This tendency is more evident for the system with the largest natural period considered in this 417 study ($T_0=2$ sec). From Figures 10 and 11 (medium and rigid soil) an analogous behavior can be 418 observed.

421 Figure 9 Maximum variability of DRF ($\Delta(\eta)$) with system damping ratio for soft soil; T₀ is the system natural period.

Figure 10 Maximum variability of DRF ($\Delta(\eta)$) with system damping ratio for medium soil; T₀ is the system natural period.

Figure 11 Maximum variability of DRF ($\Delta(\eta)$) with system damping ratio for rigid soil; T₀ is the system natural period.

Figure 12 shows the maximum DRF variability $\Delta(\eta)$ as damping ratio increases. The different colored lines correspond to the 4 structural periods analyzed, while the three symbols on the curves identify the three soil types. The variability of DRF with GMD is influenced by the natural periods of the system, by the damping ratio and by the soil type. The greater variability is for deformable systems on rigid soils and generally in the range of low damping ratio values, although a precise damping value at which the maximum variability is obtained can be identified. For rigid soil, the maximum DRF variability $\Delta(\eta)$ is 0.125 for $\xi = 0.2$.

437

434

438 **6. Proposed DRF formulation**

439 In this section a novel formulation for the DRF useful for practical application, which, in addition to

440 the period and the damping, also accounts for the effects of GMD and soil characteristics is furnished:

441
$$DRF(\xi, T_0, T_{5-95}) = \left(\frac{1 + \psi(T_0) \left(\frac{T_{5-95}}{T_o}\right) \xi}{1 + \psi(T_0) \left(\frac{T_{5-95}}{T_o}\right) 0.05}\right)^{g(T_0)}$$
(39)

- $443 \qquad \psi(T_0) = \alpha e^{-\beta T_0} \tag{40}$
- $444 \qquad \mathcal{G}(T_0) = \chi + \delta T_0 \tag{41}$

445 Nonlinear multiple regressions are carried out using a Matlab code [67] to acquire the relationship 446 that assures the best-fit of the DRF with the influence of the soil type, GMD, damping ratio and 447 natural period. The parameters in Eqs. (40) and (41) are given in Table 2.

In order to assess the efficiency of developed regression, first a comparison with results of stochastic analysis is shown. Figures 13-15 show the comparison between the proposed formulation and the results from the stochastic analysis for different soils. The dashed line is the proposed formulation while the continuous line is the result obtained by the stochastic analysis. A very good agreement is noticeable for rigid soil and medium soil whereas for soft soil some discrepancies can be observed in the range of high natural periods. For rigid soil, except for $T_0=0.5$ sec, the curves are practically coincident each other.

Table 2 Parameters in equations (40) and (41) for different soil types

Soil type	α	β	χ	δ
Rigid	16.3450	0.4626	0.4626	-0.6286
Medium	18.9182	0.5615	0.0677	-0.6259
Soft	171.8278	2.0195	-0.1364	-0.3302

457

464

467

465 Figure 15 Comparison between proposed formulation (Dashed line) and results from stochastic analysis (continuous line) for DRF
 466 (η) in case of soft soil; ξ is the damping ratio.

Finally, it would be interesting to compare the proposed formulation with results performed by other studies. However as explained in the introduction, there are not studies which consider simultaneously the effect of soil type and GMD on DRF. Therefore, a possibility is to compare the results attained
by proposed formulation with results reported in [69], in which only the influence of damping ratio,
natural period and duration, but not type of soil, is considered.

473 The results of this comparison are shown for different soils in Figures 16-18. The comparison shows

474 that in some cases the Zhou's formula overestimates the value of the DRF compared to the proposed

475 formulation. This is generally true for low natural periods and for low damping. The formulations

476 proposed, on the contrary, are in good agreement for $T_0=2.0$ s and for high damping ratio.

478 Figure 16 Comparison between proposed formulation (Dashed line) and results in [69] in case of rigid soil; ξ is the damping ratio.
479

ratio.

Figure 18 Comparison between proposed formulation (Dashed line) and results in [69] in case of soft soil

487 The results obtained from this work have a practical relevance in seismic engineering applications as 488 they allow a more accurate evaluation of the DRF, which accounts also for soil type influence, with 489 respect to other formulation existing in literature, and therefore it furnishes design forces on structures 490 in a more accurate way. One should remind that in practical applications, the effective GMD can be 491 evaluated by existing formulations [70] for a given earthquake scenario that is characterized by 492 parameters such as magnitude, epicentral distance and soil type and therefore the DRF factor can be 493 calculated by proposed formulation for a particular value of damping at any specific period of the 494 structure.

495

496 **7.** Conclusions

In this study, a combined evaluation of DRF sensitivity to ground motion duration (GMD), soil type, damping ratio and natural period has been studied; the peak theory of stochastic processes is at the base of the proposed procedure. This theory models the seismic excitation by a non-stationary process characterized by means of a stationary predominant frequency and a given bandwidth. Parameters of modulation function have been identified in order to represent earthquake with different effective durations. The following conclusions can be given on the base of the obtained results. In detail:

- DRF decreases with the increasing of damping ratio. Moreover, DRF is significantly
 dependent on the vibration period, reaching a minimum for natural period equal to earthquake
 predominant period;
- the effective duration influences DRF: as effective duration increases, DRF decreases.
 However, this variability is evident in the first part of the effective GMD for reaching the
 steady state response in the final part. For GMDs larger than 20 s, the DRF tends to an
 asymptotic final value and there are no significant differences between them (the same result
 for different GMDs).
- the variability of DRF with GMD concerns especially deformable systems (in the study T₀=2 sec is considered) with low damping ratio and becomes negligible for rigid structures (T₀=2) with high damping ratio.
- the variability of DRF with GMD cis greater for small damping ratio ($\xi = 0.10$) and reduces 515 as the damping ration increases.
- DRF depends also on ground type and a larger sensitivity is observed for rigid soil. For
 example, for this soil the variation of DRF can amount to 0.125 and the implication on
 practical application can be relevant.

519 Based on conducted stochastic analyses a simple formulation for DRF evaluation, which accounts of 520 effective duration, soil type, damping ratio and natural period of structure has been given. This study 521 gives results with great relevance in structural applications because it emerges that as well as the 522 earthquake GMD must be considered for damage structural evaluation it should be considered also 523 in the evaluation of DRF to avoid an undervaluation of reducing factor of structural seismic forces. 524 This aspect is more relevant for deformable structures on rigid soil and with low damping ratio. The 525 proposed formulation for the DRF, which accounts in addition to the period and the damping also 526 for the effects of the GMD and soil characteristics, results therefore useful for practical applications. 527
